ABSTRACT: Zebrafish *Danio rerio* are important models for biomedical research, and thus, there is an increased concern about diseases afflicting them. Here we describe infections by *Pleistophora hyphessobryconis* (Microsporidia) in zebrafish from 3 laboratories. As reported in other aquarium fishes, affected zebrafish exhibited massive infections in the skeletal muscle, with no involvement of smooth or cardiac muscle. In addition, numerous spores within macrophages were observed in the visceral organs, including the ovaries. Transmission studies and ribosomal RNA (rRNA) gene sequence comparisons confirmed that the parasite from zebrafish was *P. hyphessobryconis* as described from neon tetra *Paracheirodon innesi*. Ten 15 d old zebrafish were exposed to *P. hyphessobryconis* collected from 1 infected neon tetra, and 7 of 10 fish became infected. Comparison of *P. hyphessobryconis* small subunit rRNA gene sequence from neon tetra with that obtained from zebrafish was nearly identical, with <1% difference. Given the severity of infections, *P. hyphessobryconis* should be added to the list of pathogens that should be avoided in zebrafish research facilities, and it would be prudent to avoid mixing zebrafish used in research with other aquarium fishes.

KEY WORDS: Zebrafish · Microsporidia · *Pleistophora hyphessobryconis*

INTRODUCTION

The zebrafish *Danio rerio* is an important research model for the study of infectious disease (Dooley & Zon 2000), developmental and genetic biology (Grunwald & Eisen 2002, Ackermann & Paw 2003), cancer (Amatruda et al. 2002), immunology (Yoder et al. 2002, Trede et al. 2004), toxicology (Hill et al. 2005), and drug discovery (Zon & Peterson 2005). Their small size, relative ease of husbandry, large research community, and *ex vivo* development of transparent embryos makes them an amenable model for such studies. As a result, numerous laboratory colonies have been established containing wild-type, mutant, and transgenic strains with a wide variety of genetic backgrounds.

Unfortunately, as is the case with any animal model, the zebrafish can be afflicted with a number of diseases, potentially confounding experimental results and causing growing concern among investigators. The most common infectious diseases found in laboratory zebrafish are mycobacteriosis (Kent et al. 2004) and microsporidiosis caused by the microsporidian parasite *Pseudoloma neurophilia*. As the name implies, the microsporidium infects neural tissue in the brain and spinal cord of zebrafish (Matthews et al. 2001).

We recently detected another microsporidium in zebrafish: *Pleistophora hyphessobryconis*. This is the causative agent of 'neon tetra disease,' which targets the skeletal muscle of many aquarium fishes. The primary and type host is the neon tetra *Paracheirodon innesi* (Characiformes: Characidae). However, this

*Email: justin.sanders@oregonstate.edu

microsporidium shows broad host specificity, and has been reported from many species of aquarium fishes in several families (Characidae, Cyprinidae, Cyprinodontidae, Poeciliidae, Cichlidae), including *Danio rerio* and *D. nigrofasciatus* (Steffens 1962). Some host range reports of this parasite were derived from cross transmission studies (Canning et al. 1986), but most reports regarding the host range were from observations of naturally infected fishes. Therefore, it is conceivable that some of these infections may have been caused by other related, undescribed species that are morphologically indistinguishable.

We detected severe muscle infections of *Pleistophora hypnessobryconis* (Lom & Dyková 1992, Shaw & Kent 1999) in zebrafish from 3 separate research facilities. We report here on the case histories, including macroscopic and histological changes associated with the infection in laboratory zebrafish. We demonstrate that the parasite recently found in zebrafish from research facilities was *P. hypnessobryconis* by conducting cross transmission experiments and rRNA gene sequence comparisons with *P. hypnessobryconis* obtained from the type host, neon tetra.

MATERIALS AND METHODS

Case histories. Zebrafish from 3 research facilities were examined by histology either as part of routine health screening or because fish exhibited clinical disease. The index case (at Lab 1) was evaluated by 2 of the authors (D.N. and J.B.), and the specimens from the other 2 facilities were submitted to the Zebrafish International Resource Center (ZIRC) diagnostic service (<http://zebrafish.org/zirc/health/index.php>). Information regarding fish husbandry and quarantine procedures was provided by the submitting client.

Histology. Fish were preserved in either 10% buffered formalin (Lab 1) or Dietrich's fixative (Labs 2 and 3) and processed for routine histology. Transverse sections were made of the fish from Lab 1; sagittal sections were prepared of the fish from Labs 2 and 3. All sections were stained with hematoxylin and eosin. Additional tissue sections of the one infected fish from Lab 1 were stained with Lillie-Twort Gram stain (Culling 1974), and sections from several infected fish from Lab 3 were also stained with Accustain™, (Sigma-Aldrich), a commercial Brown-Hopps stain.

rRNA gene sequencing. After diagnosis of the infection by histology in several fish from Lab 3, additional live fish were euthanized and skeletal muscle was examined by wet mount. Infected muscle tissues from 3 fish were processed for sequencing. Using the QIAgen Blood and Tissue kit, ~25 mg of muscle tissue was extracted following the manufacturer's protocol for

extraction from tissue with an initial proteinase K digestion at 56°C for 3 h. Approximately 50 juvenile neon tetras with a suspected history of the infection were obtained from a private retail fish store in the Corvallis, Oregon area, USA. Muscle tissue from 1 infected fish was frozen and processed for sequencing as above.

PCR was performed using the general microsporidian small subunit rRNA gene primers V1F (5'-CAC CAG GTT GAT TCT GCC TGA C-3') and 1492R (5'-GTT ACC TTG TTA CGA CTT-3'). Amplifications were performed on a Peltier 200 thermocycler (MJ Research) with an initial denaturation at 94°C for 2 min, 35 cycles at 94°C for 1 min, 55°C for 1 min, and 68°C for 1 min with a final extension at 68°C for 7 min. PCR products were cloned into TOPO TA Cloning vectors (Invitrogen) and sequenced in both directions using primers flanking the inserted sequence. To exclude concomitant *Pseudoloma neurophilia* infection, a reverse primer was designed using the Primer-BLAST program available online from the National Center for Biotechnology Information (NCBI; <http://www3.ncbi.nlm.nih.gov/>). The novel primer, PleistR (5'-TCT CGC TTG TTC GCG CCT GA-3'), was used with the forward primer, V1F, to perform the PCR on samples from Lab 3 using the same thermocycling conditions as described above. PCR products from these samples were sequenced directly. All DNA analyzed in the study was sequenced on an ABI Prism®3730 Genetic Analyzer with the BigDye® Terminator v. 3.1 Cycle Sequencing kit (Applied Biosystems).

Phylogenetic analysis. The 16S rRNA gene sequence of *Pleistophora hypnessobryconis* was aligned with several *Pleistophora* sequences and other closely related genera returned by BLAST query of the GenBank database (Altschul et al. 1990) using the ClustalW2 software (Larkin et al. 2007). *Pseudoloma neurophilia* and *Glugea anomala* (Microsporidia) were selected as outgroup species. The jModelTest software (Posada & Buckley 2004) was used to determine the most likely model of sequence evolution for the dataset, and phylogenetic analyses were performed using Bayesian inference as implemented in MrBayes3.1.2 (Huelsenbeck et al. 2001) and maximum likelihood algorithms (Guindon et al. 2009) as implemented in the PHYML webserver (www.atgc-montpellier.fr/phyml/). MrBayes was run using the General Time Reversible (GTR) model of nucleotide substitution with δ -distributed rate variation across sites and a proportion of invariable sites (GTR I + G) for 1 000 000 generations. PHYML was run using the GTR model of nucleotide substitution, and bootstrap support was based on 100 replicates.

The following sequences were obtained from GenBank and used for alignment and subsequent phylo-

genetic analysis: *Pleistophora ovariae* (AJ252955.1), *P. mirandellae* (AJ252954.1), *Ovipleistophora mirandellae* (AF356223.1), *Heterosporis anguillarum* (AF387331.1), *P. mulleri* (AJ438985.1), *P. hippoglossoides* (AJ252953.1), *Pleistophora* sp. (AJ252957.1), *P. typicalis* (AJ252956.1), *P. anguillarum* (U47052.1), *Pleistophora* sp. 2 (AF044389.1), *Trachipleistophora* (AJ002605.1), *Vavraia culicis* (AJ252961.1), *Pleistophora* sp. 3 (AF044390.1), *G. anomala* (AF056016.1), *G. stephani* (AF056015.1), *G. atherinae* (U15987.1), *Loma acerinae* (AJ252951.1), *Pleistophora* sp. 1 (AF044394.1), and *Pseudoloma neurophilia* (AF322654.1).

Transmission studies. All fish were maintained and treated humanely, and the study protocol was conducted with approval from the Oregon State University Institutional Animal Care and Use Committee (ACUP# 3652).

Two groups of 15 d old AB zebrafish (10 fish group⁻¹) were obtained from the Sinnhuber Aquatic Research Laboratory, Oregon State University, and each group was placed into a 1.5 l tank. Spore counts were obtained by a hemocytometer. Homogenized muscle tissue containing 50 000 spores from a heavily infected neon tetra was added to the tank of 1 group. The other group was held as an unexposed control. Tanks remained static for 12 h postexposure after which water flow was slowly applied. Fish were held in a flow-through system supplied by ~100 ml h⁻¹ of dechlorinated tap water heated to 28°C and fed Zeigler® Larval Diet twice daily. After 30 d, all fish were euthanized by an overdose of tricaine methanesulfate (MS-222) and processed for histology. In addition, 2 moribund fish from the parasite exposed group were collected at 20 d postexposure and examined by wet mount.

RESULTS

Case history: Lab 1

Zebrafish at this facility had been maintained as a closed colony for several years. In an effort to add genetic diversity to this colony, a group of ~400 adult zebrafish was purchased in June 2006 from a commercial wholesale vendor that primarily supplies pet stores with various species of tropical fish. The new fish were held in quarantine for 90 d, and no disease problems were noted during this time. While in quarantine, the new fish were segregated from the other fish in a circular 321.8 l tank with a continuous flow-through of fresh, non-recycled water. The water source was the same as that used for the established research colony: a mixture of reverse-osmosis filtered municipal water and water from a deep on-site well. The fish were provided with the same food as that given to the adult fish

in the established colony, consisting of dry flake food (TetraMin tropical fish flake food) twice daily and live brine shrimp once daily. At the end of the quarantine period, a female fish from the recently purchased group was mated with a male fish from the long-established colony. The eggs/developing embryos were bleach disinfected by immersion in a water bath containing 30 ppm sodium hypochlorite for 2 min after which the embryos were transferred to 10 gal (~38 l) aquariums where they developed into fry. These aquariums all shared the same recirculating water system. The food provided to the fry consisted of live *Tetrahymena* on Days 1 to 4 post hatching, live microworms on Days 3 to 21, and live brine shrimp on Days 6 to 21. After Day 21, the fish were fed flake food and brine shrimp as described above for adult zebrafish. All live invertebrates fed to the fish were from cultures maintained at Lab 1.

At ~1 mo of age, the young fish were transferred from the 10 gal (~38 l) aquariums to a single 85 gal (~322 l) circular tank with a continuous flow-through of fresh, non-recycled water. In October 2007 (i.e. at 13 mo of age), 8 apparently healthy fish from this group were selected at random for routine health assessment and 1 of these fish was found through histologic examination to be infected with microsporidian parasites morphologically consistent with *Pleistophora hypnessobryconis*. Over several wk after the detection of the infected fish, the remaining 135 fish of this sibling co-hort group were euthanized and examined grossly (98 fish) and/or histologically (37 fish). No other infected fish were detected in this group and there have not been any subsequent cases detected in Lab 1.

Case history: Lab 2

A microsporidian infection consistent with *Pleistophora hypnessobryconis* was detected in 1 of 30 moribund fish submitted to the diagnostic laboratory of ZIRC. The fish was a wild-type strain purchased from a commercial tropical fish vendor and was being held in quarantine at the time it became ill. The fish were hatched September 2008 and submitted to the diagnostic laboratory March 2009.

Case history: Lab 3

The infection was initially detected in 2 of 13 moribund fish submitted to the ZIRC diagnostic service in June 2009. The infected animals were 18 mo old fish from the CG1 strain: a clonal, homozygous strain of fish used exclusively for tissue transplantation studies and developed using AB fish obtained from a laboratory

colony and a brass mutant line obtained from a pet store (Mizgireuv & Revskoy 2006).

The 'founding' CG1 fish in Lab 3 (i.e. grandparents of the infected fish) were originally imported from another institution into Lab 3's quarantine facility as surface-disinfected eggs. This quarantine facility is physically separated from the main fish holding room, with isolated recirculating water systems, ultraviolet treatment of effluent post-filtration, restricted access, and dedicated equipment. Fish are moved from quarantine into the main facility as eggs after being disinfected in 30 ppm sodium hypochlorite for 2 min and transferred to sterile water.

After this discovery, more fish in this facility were screened for the parasite. First, 10 live fish from the same stock in which the initial infection was detected were shipped live to Oregon State University for histology. All of these animals, many of which presented obvious clinical signs of infection, tested positive for the parasite by histology. An additional 13 ind. from the subsequent (F3) generation of CG1 in this facility were examined and confirmed as positive for the infection by histology. Finally, infections were detected in 3 more fish in August 2009, 2 more from the F3 generation of the CG1 strain and another fish from a separate population of WIK strain zebrafish. All 3 of these animals had been exposed to sublethal doses of gamma radiation to suppress the immune system before tissue transplantation (Traver et al. 2004). The WIK fish in this facility were imported as described for the CGI line and had been maintained internally for many generations, with no known history of exposure to fish outside of the colony.

In October 2009, 46 AB strain fish from Lab 3 were submitted to ZIRC for histological analysis as part of the parent institution's health sentinel monitoring program. These fish had been directly imported into the facility from ZIRC as surface disinfected eggs and reared in small groups on each of the facility's recirculating systems. At 6 mo, all of these fish were euthanized and examined by histology. A single fish from this group was positive for *Pleistophora hypnessobryconis*, and it had been housed in the same rack as the infected CG1 fish.

Macroscopic changes and clinical signs

The 1 infected fish from Lab 1 showed no obvious clinical or macroscopic changes. The 1 infected fish from Lab 2 was sluggish, appeared bloated, and exhibited a white area in the integument below the dorsal fin that was obvious in the swimming fish when examined from above.

In Lab 3, large, depigmented regions in the central dorsal fin area were observed in infected fish while still

swimming in tanks. Some fish also displayed spinal curvatures. Examination of infected fish with a dissecting microscope revealed multifocal to coalescing white-gray, slightly raised regions where the skin appeared depigmented (Fig 1). Removal of the skin showed that the underlying skeletal muscle was white, soft, and edematous (Fig 1). The 1 positive AB fish from the Lab 3 sentinel group appeared normal when euthanized.

Microscopic examinations

Wet mount preparations of skeletal muscle from infected fish revealed numerous sporophorous vesicles, many of which contained fully developed spores. Spores in wet mounts were 7 by 4 μm ($n = 20$), and contained a prominent posterior vacuole measuring ~ 3 by 3 μm (Fig 2). Histopathologic changes were consistent from all 3 laboratories and thus are described together. As previously described by other investigators (Schäperclaus 1941, Dyková & Lom 1980, Canning et al. 1986), intramuscular infection by *Pleistophora hypnessobryconis* microsporidian organisms caused disruption of skeletal muscle comprising myomeric units. However, in several of the fish examined as a part of this study, the severity of infection was much more pronounced and was associated with severe chronic inflammation. In these fish, on average, 50 to 80% of affected skeletal muscle myofibers displayed extensive liquefactive necrosis and marked expansion by the intramuscular microsporidian parasite. Skeletal muscle degeneration, denoted by loss of cross-striations as well as fragmented, hyper eosinophilic myofibers and centralized nuclei, was also observed

Fig. 1. *Danio rerio*. Zebrafish infected with *Pleistophora hypnessobryconis*. (A) Mottled appearance with light areas (arrows) on flanks. (B) Same fish with skin removed, exhibiting opaque regions in muscle (arrows) representing massive infection. Scale bar = 500 μm

Fig. 2. *Danio rerio*. Wet mount of *Pleistophora hyphessobryconis* spores. Note prominent posterior vacuole (arrow). Scale bar = 10 μ m

among the affected myofibers. In sections, muscle myofibers contained from 2 to 30 plus *P. hyphessobryconis* organisms at varying developmental stages, ranging from rounded-up multinucleated meronts to sporophorous vesicles containing sporoblast mother cells and vesicles with mature spores (Fig. 3). The affected skeletal muscle myofibers were frequently surrounded by large numbers of intermixed histiocytes and lymphocytes with fewer eosinophilic granular cells, which tracked along the endomysial connective tissue and were accompanied by marked endomysial edema that widely separated myofibers. Regenerating myofibers characterized by enhanced sarcoplasmic basophilia and nuclear rowing were frequently adjacent to many of the necrotic myofibers (data not shown). Numerous liberated mature spores within the endomysial spaces were surrounded by dense aggregates of histiocytes and lymphocytes (Fig. 3B). Phagocytized mature spores were occasionally seen within activated histiocytes.

The parasitic infection in the single fish from Lab 1 was limited to the skeletal muscles; however, in the fish from the other 2 laboratories, spores within phagocytes were also detected in various other organs, including the kidney interstitium, spleen, ovaries, intestine, and mesenteries. Massive numbers of spores within phagocytes were frequently observed in the connective tissues of the ovary, but never within ova (Fig. 3G). Aggregates of spores were observed in all layers of the intestine, extending through the serosal surface and into mesenteric connective tissue. Smooth and cardiac muscle were not affected in any of the fish examined. Both Gram stain methods were effective for

distinguishing spores. With the Accustain method, mature spores stained deep blue while immature spores appeared to take up less of the stain (Fig. 3D). With the Lillie-Twort method, fully formed spores stained deep blue to purple (Fig. 3E).

All 7 of the fish from Lab 3 examined by histology exhibited a mixed infection with *Pseudoloma neurophilia* (Fig. 3C). This microsporidium was easily distinguished from *Pleistophora hyphessobryconis* by its location in the central nervous system and lack of a sporophorous vesicle with a prominent wall.

Ribosomal DNA sequence

Of the small subunit rRNA gene, 1361 bp was sequenced from *Pleistophora hyphessobryconis* obtained from an infected neon tetra and is available in the GenBank database under accession number GU126672. The maximum likelihood and Bayesian analyses produced phylogenetic trees with identical topology (Fig. 4). The topology is also consistent with other phylogenetic analyses of fish microsporidian parasites (Nilsen 2000). *P. hyphessobryconis* was placed in the clade containing *Ovipleistophora ovariae* and *O. mirandellae* as well as *Heterosporis anguillarum*.

A total of 1224 bp (position 1 to 1224) of the small subunit rRNA gene was sequenced from *Pleistophora hyphessobryconis* obtained from 3 zebrafish submitted by Lab 3. All 3 of these sequences were identical, with no insertions/deletions nor transitions/transversions. Comparisons of the 1224 bp subset of the sequence obtained from the neon tetra and the 3 sequences obtained from zebrafish showed no insertions/deletions and 2 transitions: at site 149 (T to C) and at site 180 (G to A) for an overall paired distance of 0.002.

Transmission

Both moribund zebrafish collected from the group exposed to infected neon tetra tissue exhibited massive muscle infections based on wet mount observations at 20 d postexposure. Histological examination of the remaining fish collected at 30 d showed infections in 5 of 8 fish. These fish had light infections exhibiting various stages of development.

DISCUSSION

Identification and taxonomy

Pleistophora hyphessobryconis infections in aquarium fishes have been documented for many decades

Fig. 3. *Danio rerio*. Histological sections of zebrafish infected with *Pleistophora hyphessobryconis*. (A) Numerous sporophorous vesicles with spores and developmental stages within myocytes. (B) Spores in phagocytes associated with chronic infections and myolysis (arrows). (C) Mixed infection with *P. hyphessobryconis* in muscle and xenomas of *Pseudoloma neurophilia* in spinal cord (arrows). (D) Meronts (m) and developing (sp) and mature spores in sporophorous vesicles. Some fully developed spores stain deep blue (arrows). (E) Mature spores stain deep blue to purple (arrows); developmental stages are pink (arrow heads). (F) Numerous spores (arrows) throughout all layers of the intestine and mesenteries. (G) Masses of spores in phagocytes (arrows) in ovaries. Scale bars: (A,B,C,F) = 20 μ m, (D,E,G) = 10 μ m. Stains: (A,B) = hematoxylin and eosin, (C,D,F,G) = Accustain Gram, (E) = Lillie-Twort Gram

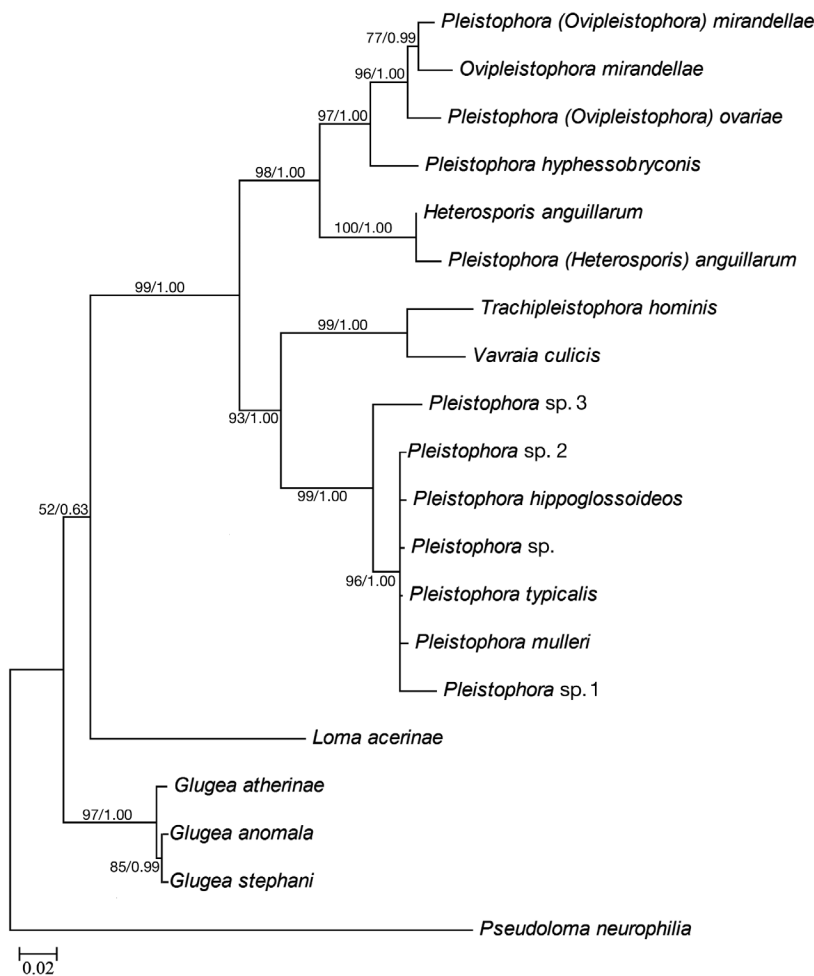

Fig. 4. Phylogenetic tree of *Pleistophora hyphessobryconis* obtained from neon tetra and related microsporidia. 1361 bp small subunit rRNA gene sequences from 20 microsporidia infecting fish were used to reconstruct phylogeny. Maximum likelihood tree is shown. Branch numbers: maximum likelihood bootstrap support based on 100 replicates/Bayesian posterior probabilities. Genus names: as recorded in GenBank with new genus designations in parentheses. Microsporidian parasite *Pseudoloma neurophilia* was selected as an outgroup taxa. Scale bar represents number of base substitutions per site

since the original description in 1941 by Schäperclaus (Schäperclaus 1941). Unusually for microsporidia, the parasite shows remarkably broad host specificity, infecting some 20 species of freshwater fishes in 4 orders (Steffens 1962, Schäperclaus 1991, Lom & Dyková 1992). Among those are zebrafish (Opitz 1942) and the dwarf danio *Danio nigrofasciatus* (Spence et al. 2008). Here we found the infection in 3 separate zebrafish research colonies with no known movement of fish between the facilities. Confirmation of host ranges of parasites with limited morphological characters (such as Microsporidia) often requires cross transmission studies or sequence comparisons. There are reports of experimental transmission experiments of *P.*

hyphessobryconis amongst various fishes (Canning et al. 1986). Here we confirmed that the infection in zebrafish was *P. hyphessobryconis* by histology, rRNA gene sequence comparisons, and cross transmission studies.

We found <1% (0.002) difference in small subunit rRNA gene sequence between parasites from the type host (the neon tetra) and from zebrafish. This is consistent with intraspecific variation in this region of the small subunit rRNA for other *Pleistophora* spp. and related microsporidia. The intraspecific pairwise distance between other available sequences from multiple individuals in GenBank are as follows: *P. typicalis*, 0.013; *Heterosporis* (syn *Pleistophora*) *anguillarum*, 0.02; *Ovipleistophora* (syn, *Pleistophora*) *mirandellae*, 0.069; and *P. mulleri*, 0.007. Further, we found an average pairwise interspecific distance of 0.198 with all members of the genera *Pleistophora*, *Ovipleistophora*, and *Heterosporis* with sequences published in GenBank. The minor, but consistent, differences seen between the 3 zebrafish sequences compared to that of neon tetra might suggest different strains of the parasite. Regardless, the parasite from neon tetra was easily transmitted to zebrafish. Our findings agree with previous transmission studies, confirming the broad host specificity of this microsporidium (Canning et al. 1986).

It was noted previously that the genus *Pleistophora* does not form a monophyletic clade (Nilsen et al. 1998). In fact, ultrastructural characterization and molecular analyses of

the small subunit rRNA gene sequences have resulted in the movement of *P. mirandellae* (Pekkarinen et al. 2002) and *P. anguillarum* (Lom et al. 2000) to new genera (*Ovipleistophora* and *Heterosporis*, respectively). Prior ultrastructural descriptions of *P. hyphessobryconis* (Lom & Corliss 1967) confirm the placement of this species in the genus *Pleistophora* as redescribed by Canning & Nicholas (1980). However, phylogenetic analyses of *P. hyphessobryconis* place it more closely to both *O. mirandellae* and *H. anguillarum* than *P. typicalis*, the type species described for the genus (Fig. 4). Interestingly, unlike the members of *Ovipleistophora*, this species does not infect oocytes but rather myocytes as does the type species of this genus, *P. typicalis*.

Comprehensive analysis of the genus is beyond the scope of this study, but further investigation appears to be needed.

Transmission

The 3 facilities had no history of sharing fish and are located in different areas of the United States. Thus, we presume that the infections arose in 3 independent instances by exposure to other species of infected aquarium fishes. Indeed, the CG1 line was actually derived from zebrafish purchased from a pet store (Mizgireuv & Revskoy 2006). The affected fish from Lab 2 had also been purchased from a pet store and the maternal parent of the infected fish at Lab 1 had been purchased from a vendor that supplied fish to the commercial pet trade. Transmission of *Pleistophora hypheobryconis*, ostensibly *per os*, was achieved by placing large numbers of spores in water with fish, a method that has been used by others (Canning et al. 1986). As with other microsporidia, it is assumed that infection is initiated by ingestion of spores. Spores released from dead fish are a likely source of infection, but could also be released from the intestines. Schäperclaus (1941) suggested that spores may be released from the skin or urinary tract of infected fish.

Zebrafish spawn frequently within aquaria, and tank mates quickly eat available eggs (Lawrence 2007, Spence et al. 2008). Although spores were not found within eggs, the massive numbers seen within ovaries of some infected zebrafish suggest that infectious spores could be released during spawning and would thus be available to fish feeding on eggs or to infect the next generation of fish. Maternal transmission, including true vertical transmission within eggs, has been verified or implicated for other microsporidia of fishes (Docker et al. 1997, Kent & Bishop-Stewart 2003, Phelps & Goodwin 2008). Schäperclaus (1941) suggested the possibility of maternal transmission as he found infections in 8 d old neon tetras derived from infected parents. Once established in zebrafish, it is conceivable that the infection could be maternally transferred to the next generation. This could even occur with spores outside the egg as microsporidian spores are very resistant to chlorine (Ferguson et al. 2007). This provides one explanation for the occurrence of the infection in fish derived from surface-disinfected eggs. Alternatively, these fish may have become infected by an unrecognized breach in biosecurity protocols.

The infected fish from Lab 1 was the 13 mo old offspring of a female fish that had been purchased from an outside vendor and brought into the laboratory. If this fish was infected as an embryo, this would mean

that the fish was subclinically infected for more than 1 yr. All of the fish purchased from the vendor had been removed from Lab 1 more than 7 mo before the infected fish was detected. Even if the fish had not been infected as an embryo but instead at a later time through accidental cross-contamination with an infected fish from the group purchased from the vendor, it indicates that this fish was subclinically infected for more than 7 mo.

As with other microsporidian infections, it is likely that immune status influences susceptibility of zebrafish to *Pleistophora hypheobryconis*. Recently, Ramsay et al. (2009) showed that stress enhances infections of *Pseudoloma neurophilia* in zebrafish. Infections by *P. hypheobryconis* were widespread in only one strain (CG1) in one of the labs with the infection suggesting that this line may be particularly susceptible to the parasite. The microsporidium was also found in fish (CG1 and WIK) that were irradiated and thus were immune compromised. Although immune status likely affects the susceptibility and progression of the disease in zebrafish, apparently immunocompetent fish can become infected as demonstrated by reports of *P. hypheobryconis* in zebrafish from aquaria (Opitz 1942, Steffens 1962), and experimental infections in presumably healthy zebrafish reported here. The latter were exposed at 15 d old, a time at which fish have innate immunity but adaptive immunity has not fully developed (Lam et al. 2004, Trede et al. 2004).

Pathology

The infection in zebrafish was consistent with reports from neon tetras and other species (Dyková & Lom 1980, Canning et al. 1986, Schäperclaus 1991). The most remarkable pathological feature of *Pleistophora hypheobryconis* is the severe intensity of infection in the skeletal muscle, with well over half of the myofibers containing numerous spores and developmental stages in some fish. Parasites within myocytes were not associated with inflammation; however, mature spores released from degenerate myofibers into interstitial spaces were consistently associated with inflammation, and these liberated spores were often engulfed by phagocytes. This is similar to that seen with other intramuscular parasites of fishes, such as *Kudoa thyrsites* of salmon (Moran et al. 1999). Likewise, other microsporidia show a similar sequelae of infection in which spores elicit significant inflammation only after they are released from their intracellular environment within xenomas (Dyková & Lom 1980, Kent & Speare 2005). Microsporidian spores remain intact within phagocytes, and thus may be transported to sites beyond where they originally developed (Kent et al. 1999). The occurrence of large numbers of

spores of *P. hypnessobryconis* within phagocytes in organs other than the skeletal muscle, as seen in the present study, has been previously observed (Lom & Dyková 1992). Spores of microsporidia are Gram positive in histological sections (Gardiner et al. 1998, Bruno et al. 2006). Both Lilly-Twort and Accustain Gram stains were very effective in demonstrating spores and particularly useful for visualizing individual spores within visceral organs.

Some infected zebrafish exhibited concurrent infections by *Pseudoloma neurophilia*, a common microsporidian parasite of zebrafish that demonstrates myelinotropic behavior and is directly associated with encephalomyelitis and polyneuritis involving the peripheral nerves and spinal nerve roots. The 2 microsporidian infections can be easily differentiated by histology. Skeletal muscle is the primary site of development of *Pleistophora hypnessobryconis*, with prominent developmental stages and spores within thick-walled sporophorous vesicles. In contrast, the central and peripheral nervous systems are the primary sites of infection for *P. neurophilia* and finding individual spores or xenomas in extraneural tissue is uncommon. In cases of myositis attributed to *P. neurophilia*, few spores are found in the muscle, but these are frequently associated with severe chronic inflammation (Matthews et al. 2001). In the case of coinfections, the opaque, depigmented muscle lesions were clearly caused by *P. hypnessobryconis*. However, it is possible that *P. neurophilia* contributed to other clinical changes.

Given the potential for severe infections and long-term subclinical chronic infections, *Pleistophora hypnessobryconis* should be added to the list of pathogens that should be avoided in zebrafish research facilities. As suggested for *Pseudoloma neurophilia* (Kent et al. 2009), the most feasible strategy would be to hold brood fish in quarantine and screen them and their progeny for the infection using a PCR test specific to the parasite. Sentinel fish programs and sampling of moribund fish are also recommended as a means of surveillance of colony health. Notably, 2 of these cases were from fish that had been in contact with commercial pet store fish. It would be prudent to not mix zebrafish used in research with other aquarium fishes. Further studies on the role of maternal transmission, susceptibility of spores to disinfectants, and the role of age and fish strain in severity of disease are all warranted.

Acknowledgements. This study was supported by grants from the National Institutes of Health (NIH NCRR 5R24RR017386-02 and NIH NCRR P40 RR12546-03S1).
